Abstract. This review covers the domino reactions which involve, at least, both Pd-catalyzed dehydrogenation of carbonyl compounds and Heck-type reactions. While the former occurs under Pd^{II}-catalysis, Pd⁰- or Pd^{II} catalyst is requested for the latter, depending on the nature of the (hetero)aryllating agent, ArX or ArH, respectively. The regeneration of Pd^{II} species is assumed by either an oxidant or the aryl halide. Proposed mechanisms are described, with, in some cases, personal comments.

1. Introduction

The synthesis of complex organic molecules via a one-pot reaction corresponds to the sequential addition of the reactants to the reaction flask, possibly under experimental conditions depending of each reactant, followed by work-up and purification.^[1] This procedure is more compatible with economic and ecological constraints than the step by step synthesis, which is time-consuming, requires extraction and purification steps leading to large amounts of waste.

The most attractive procedure is however the domino reaction which, according to Tietze, leads to the formation of “several bonds in one sequence without isolating the intermediates, changing the reaction conditions, or adding reagents”.^[2,3] According to Fogg and dos Santos,^[4] the appellation “tandem” could be attributed to some of these reactions but Tietze suggested not to use it, because “Tandem means two at the same time and does not describe a time-resolved transformation”.^[5] The aim of the present review is to highlight domino reactions which implicate two Pd-catalyzed reactions: dehydrogenation of a carbonyl compound and Heck-type reaction.^[6] Pd catalyst being used in both reactions, the term “auto-tandem catalysis” has been proposed for such one-pot processes^[4,7] but as Tietze,^[5] we are not fond of it. The definition of the domino reaction^[2] leads to discard procedures involving a modification of the starting conditions in the course of the process.^[8]

α,β -Unsaturated carbonyl compounds are highly useful synthetic blocks in organic synthesis, which can be prepared from Pd^{II}-catalyzed dehydrogenation of the corresponding saturated substrates as depicted in Scheme 1.^[6a,9] Sometimes, this reaction (noted below KTR), which has been discovered by Kirschke and Theisen,^[10-12] is improperly named the Saegusa’s reaction. Indeed, Saegusa’s reaction^[13] concerns the oxidation of silyl enol ethers and related enol derivatives to α,β -unsaturated carbonyl compounds.^[14] Over-dehydrogenation of cyclohexanones may afford the corresponding phenols.^[6a,9,12,15]

Scheme 1. Pd^{II}-catalyzed dehydrogenation of carbonyl compounds (KTR).

Heck-type reactions are involved in a number of domino reactions leading to multiple C-C or C-heteroatom bonds.^[16,17] Originally, the Heck reaction (HR), independently discovered by the teams of Mizoroki,^[18] Julia^[19] and Heck,^[20] is the formation of arylalkene from the Pd⁰-catalyzed coupling of an aryl halide with an alkene (Scheme 1, path *a*). When a Pd^{II} salt is used as the starting catalyst, its in-situ reduction under the experimental conditions affords the required Pd⁰ species.^[18,20] Heck’s team, which intensively worked in this research area, also discovered the synthesis of arylalkenes via trans-metalation with Pd^{II} catalysts of organometallic reagents used as the aryl source (Scheme 1, path *b*);^[21] such procedure is often called oxidative Heck reaction (OHR).^[22] Myers’ team proposed the decarboxylative Heck reaction (DcHR), which uses arene carboxylates to form such C(sp²)-C(sp²) bonds (Scheme 1, path *c*).^[23] Another procedure, initiated by Fujiwara’s team,^[24] is the dehydrogenative Heck reaction (DHR), which involves Pd^{II}-catalyzed activation of an arene C-H bond (Scheme 1, path *d*).^[25] Intermediate **2A** may suffer either reductive Heck reaction (RHR)^[26,27] or

protonolysis (PHR)^[27-29] rather than β -H elimination to afford the arylalkyl (Scheme 1, paths *e* and *f*, respectively). Heck-type reactions also occur using alkenyl halides instead of aryl halides.^[16,20]

Scheme 2. Some Heck-type reactions: HR (path *a*), OHR (path *b*), DcHR (path *c*), DHR (path *d*), RHR (path *e*), PHR (path *f*).

2. Domino KTR + HR(s)

A number of KTR-HR(s) of aldehydes, ketones and esters have been carried out by Cheng's team using $\text{Pd}(\text{OAc})_2$ as catalyst, Na_2CO_3 as the base and an excess of aryl iodides at $120\text{ }^\circ\text{C}$ in DMSO under nitrogen.^[30] The excess of ArI regenerates Pd^{II} species from Pd^0 , as that occurs for Yoshida's Pd^{II} -catalyzed oxidation procedure of alcohols.^[31] 2-Phenylpropanal and α -substituted propiophenones reacted with a variety of aryl iodides (2.5 equiv.) leading efficiently to the corresponding β -arylated α,β -unsaturated aldehydes and ketones [Eqs (1) and (2)]. In contrast to the α -substituted propiophenones [Eq. (2)], the reaction of propiophenone afforded mainly the β -diarylation product. Such compounds were then synthesized using a large excess of ArI [Eq. (3)]. However, butyraldehyde, pentan-2-one and 1-phenylbutan-1-one, which have a β -methyl substituent, did not give the KTR-HR products [Eq. (4)]; that is surprising because their reaction could be expected from literature data.^[32,33] To give the dehydrogenative coupling products with 2-phenylpropanal and propiophenone, aryl bromides have to react in the presence of 1,4-bis(diphenylphosphino)butane and in DMF instead of DMSO (Eq. 5).^[30,34]

The formation of 17% of the 1,1-diarylation product against 26% of the 1,1,5,5-tetraarylation product from the reaction of diethyl ketone with 4-iodotoluene [Eq. (6)] suggested to Cheng and co-workers that “the dehydrogenation step is slower than the Heck reaction step”.^[30] In fact, the same type of species, $\text{ArPd}^{\text{II}}\text{I}$ or $\text{ArPd}^{\text{II}}\text{I}(\text{DMSO})_n$ ^[35] may mediate the KTR and the HR (Scheme 3), hence the competition between the two reactions.

Scheme 3. The competition between KTR and HR in the domino reaction.

The optimum conditions recently reported by the team of Xie and Shao^[36] for the synthesis of β,β -diarylacroleins from arylpropanals and aryl iodides, Ag_2CO_3 as the base^[37] in AcOH under air [Eq. (7)], differ from those above. Given the yield decrease with either the amount of the aryl iodide or using nitrogen [Eq. (7)], we devise that both ArI and O_2 ^[38] participate in the regeneration of the Pd^{II} catalyst. The authors proposed the promotion of the HR by AgI formed in the course of the process.

3. Domino KTR + OHR

Kim's team reported the synthesis of a range of 3-arylchromones from the KTR-OHR of chromanones with arylboronic acid pinacol esters.^[39] Optimum conditions arose at 100 °C in DMSO and oxygen with catalytic amounts of both Pd(OCOCF₃)₂ and 5-nitro-1,10-phenanthroline [Eq. (8)]. The cross-coupling was also efficient in DMF but other solvents such as THF, dioxane, PhMe and MeCN, or the absence of the phenanthroline ligand led mainly to the chromone (up to 72%). Under the optimum conditions, traces of 2-arylchroman-4-one, which are produced from the domino KTR-PHR, were possibly produced. Both KTR and OHR require Pd^{II} catalysis. According to the authors, oxygen assumes the catalyst regeneration,^[39] but DMSO may also participate to the process.^[40]

$R^1 = H, R^2 = H$ (93%), *p*-Me (75%), *p*-(*t*-Bu) (81%), *p*-Ph (75%), *p*-Cl (60%), *p*-Br (48%), *p*-F (70%),

$R^2 = H, R^1 = 6\text{-NO}_2$ (51%), 6-Cl (80%), 6-F (79%), 6-Me (85%), 6-OMe (73%), 7-OMe (82%),
7-OCOt-Bu (51%)

Rather similar conditions were used by Vilela, Lee and co-workers to carry out the KTR-OHR of substituted 1,3-cyclopentadiones.^[41] The authors however observed that, with Pd(OAc)₂ associated to 1,10-phenanthroline in DMF under oxygen, the yields were higher using a non-

anhydrous solvent and non-dried glassware instead of anhydrous conditions [Eq. (9)]. The authors proposed that residual water promotes the transmetalation.^[42]

4. Domino KTR + DcHR

The KTR-DcHR disclosed by Su and co-workers concerns the Pd^{II}-catalyzed cross-coupling of propiophenones with aryl carboxylic acids.^[43] The efficiency of this domino reaction is very sensitive to the structure of the substrates, hence optimum experimental conditions depending on the substitution of the aryl cores. Most reported results were obtained using a mixture of Pd(OAc)₂ and PCy₃ as the catalyst, Ag₂CO₃ as the oxidant, *n*-Bu₄NOAc·AcOH as the base in DMF or DME [Eqs (10) to (12)]. Cu(OAc)₂ or CuF₂ can be more efficient than Ag₂CO₃ for the DcHR of electron-rich and heterocyclic carboxylic acids with 1-phenylpropen-1-one [Eqs (10) and (11)]. Most substituted propiophenones leading to poor results, the authors suspected that α-H acidity varies with the substituent on the benzene ring, and proposed that adequate acids or bases have to be used, hence the use of subquantities of phenol as additive, or the change of *n*-Bu₄NOAc·AcOH for KOAc [Eq. (12)]. In fact, Buchwald and co-workers disclosed that phenol promotes the Pd-catalyzed arylation of ketone enolates with *o*-halonitroarenes, and suspected its beneficial role in the formation of palladium enolates.^[44] Thus, phenol could also promote the KTR, which also occurs via a palladium enolate.^[6a,9]

5. Domino KTR + DHR

The synthesis of 2-arylchromen-4-ones from KTR-DHR of chromanones has been described by Hong's team in 2012, using a large excess of arenes, $\text{Pd(OCOCF}_3)_2$ as the catalyst and a $\text{Cu(OCOCF}_3)_2/\text{AgOAc}$ mixture as the oxidant in pivalic acid [Eq. (13)].^[45] In contrast, the same procedure afforded the C3-product from 1-methyl-2,3-dihydroquinolin-4(1*H*)-one [Eq. (14)]. The KTR-DHR of various cyclic β -heteroatom-substituted ketones using acrylates

instead of arenes was performed under slight different experimental conditions, leading also to C3-products [Eqs (15) and (16)].

The regioselectivity of the KTR-DHR of

- chromanones with arenes [Eq. (13)]^[46] is consistent with the DHR of chromones with arenes,^[47]
- of chromanones and dihydroquinolin-4-ones [Eq. (15)] with acrylates is consistent with the DHR of chromones^[48] dihydropyranones,^[49] quinolones^[50] and cyclic enaminones^[51] with acrylates,
- 1,3-dimethyldihydropyrimidine-2,4(1H,3H)-dione [Eq. (16)] is consistent with the DHR of uracils with acrylates.^[52]

The C3-arylation of 1-methyl-2,3-dihydroquinolin-4(1*H*)-one [Eq. (14)] was unexpected.^[45] In fact, the DHR of 1-methylquinolin-4-one with fluoroarenes also led to such regioselectivity.^[53] Besides, modification of the common experimental conditions for the Pd^{II}-catalyzed cross-coupling of coumarins with arenes led to α -arylation instead of the usual β -arylation.^[54] The DHRs involve two C(sp²)-H.^[25] We suspect that the regioselectivity of the above domino reactions could depend on the C-H reacting with palladium. In the presence of acrylates, the heterocyclic substrate reacts first yielding the results depicted in Eqs (15) and (16). The arylation pathway was more subtle: C2-products as the main compounds^[46] when arenes react first [Eq. (13)] whereas C3-H of 1-methylquinolin-4(1*H*)-one is palladated^[55] before to react with benzene to afford the C3-product [Eq. (14)].

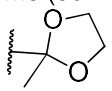

It is usually considered that the elimination of HPdX species requires the *syn* relationship between the palladium unit and the hydrogen.^[16,56] The insertion of the C=C bond into Ar-Pd^{II} species being a *syn* process,^[16,56,57] there is no *syn* relationship between the palladium unit and the hydrogen geminal to the Ar group in the intermediates formed from above chromones (Scheme 4). Thus, the arylation compound is plausibly produced via an oxo- π -allylpalladium allowing epimerization of the carbon center,^[58] or from base-assisted reductive β -H elimination^[59] (Scheme 4).^[60,61]

Scheme 4. The β -H elimination.

Su's team, who previously performed (KTR-DcHR)s [Eqs (10) to (12)],^[43] used again Pd(OAc)₂/PCy₃ and Ag₂CO₃ in DME, but with TEMPO as supplementary oxidant^[62,63] to carry out the KTR-DHR of propiophenones and 1-alkylpropanones with (hetero)arenes.^[64] With thiophenes, furans and indoles, optimum results were obtained with LiOAc or NaOAc as additional base [Eqs (17) to (19)]. The dehydrogenative cross-couplings between fluorobenzenes and propiophenones were effectively carried out with KF as the base and tetramethylene sulfoxide as ligand [Eq. (20)]. The KTR-DHR of 2,3,5,6-tetrafluoropyridine also occurred with a fair yield while that of benzene was disappointing [Eq. (20)]. It seems interesting to note the poor yield also achieved from the KTR-DHR of an unsubstituted heteroarene such as thiophene [Eq. (17)]. According to a set of experiments carried out to ascertain the formation mechanism of the arylation product, the cross-coupling arises effectively from the domino KTR-DHR, that is, successively, ketone dehydrogenation, palladoarylation, across insertion of the C=C bond into the Ar-Pd^{II} bond, and β -H elimination.

Bäckvall and Gigant disclosed an aerobic KTR-DHR procedure^[65] using an electron-transfer mediator, the iron phthalocyanine (Fe(Pc)), which facilitates the catalyst re-oxidation to its active form by oxygen (Scheme 5).^[66] Heated in AcOH containing catalytic amounts of Pd(OAc)₂(DMSO)₂, benzoquinone and Fe(Pc), a variety of substituted cyclohexanones and arenes led, under oxygen, to the corresponding β-arylated cyclohexenones except the 4-acetamidocyclohexanone which afforded a 3:2 mixture of the α- and β-arylated isomers [Eq. (21)]. Coordinating properties of the acetamido unit could explain the inversion of the regioselectivity. Unsubstituted cyclohexanone and linear aliphatic ketones are decomposed under the reaction conditions, whereas the α,β-diarylation product was obtained from indanone [Eq. (22)]. In contrast, benzosuberone was monoarylated [Eq. (23)].

6. Domino KTR + PHR

The PHR reaction can arise using aryl halides as well as arenes since both arylating agents afford the same intermediate as previously depicted in Scheme 2. Thus, (KTR-PHR)s using either one or the other have been reported.

6.1 Using aryl halides

In 2002, Hartwig's team reported that the Pd-catalyzed reaction of lithium enolate of methyl isobutyrate with thirty nine bromo(hetero)arenes afforded selectively the α -(hetero)arylation compound except with 2-bromothiophene which reacted to the α and β positions [Eq. (24)]. The authors suspected the formation of the β -compound through a " α -hydrogen elimination and reinsertion of the olefin into the metal hydride".^[67]

In 2010, Clot, Baudoin and co-workers disclosed experimental conditions leading, in most cases, to the selective β -(hetero)arylation of various ester enolates [Eq. (25)].^[68]

Subsequently, the same team related the strong dependence of both conversion and α/β selectivity on the nature of the ligand.^[69] For an example, the α/β ratio of the cross-coupling between *t*-butyl isobutyrate and 2-fluorobromobenzene was 85:15 with $\text{P}t\text{-Bu}_3$, and <2:98 with 2-dicyclohexylphosphanyl-2'-(*N,N*-dimethylamino)biphenyl [Eq. (25)]. Use of a chiral ligand led to cross-coupling products in fair yields and with enantioselectivities which remain to improve [Eq. (26)].^[68]

^a α -arylation only.

^bPlus α -arylation (68%).

^c α/β ratio: <2:98.

^dPlus α -arylation (14%).

Analysis of the reactivity of deuterated esters led the Clot and Baudoin team to exclude a direct $\beta\text{-C}(\text{sp}^3)\text{-H}$ activation and to propose a mechanism supported by computational studies.^[69] Trans-metalation of the lithium enolate with the arylpalladium complex affords palladium enolate **6A** (Scheme 6). The agnostic Pd-H liaison may favor the formation of olefin complex **6B** rather than the reductive elimination leading to the α -arylated product. Bond rotation gives isomeric complex **6C**. Subsequent insertion of the C=C bond into the H-Pd bond provides palladium homoenolate **6D** which undergoes reductive elimination to provide the β -arylated product. According to this catalytic cycle and despite the absence of free α,β -unsaturated ester, this β -arylation corresponds to a domino KTR-PHR. That led us to suspect that some other Pd-catalyzed $\beta\text{-C}(\text{sp}^3)\text{-H}$ functionalizations of carbonyl compounds could also involve an intermediate dehydrogenation reaction.^[70]

Scheme 6. Mechanism of the α - and β -arylation of alkyl isobutyrate.

Dong and Huang disclosed the β -arylation of cyclic and linear ketones as well as chromanone, with aryl iodides [Eq. (27) to (31)].^[28] Catalyzed by the $\text{Pd}(\text{OCOCF}_3)_2/\text{P}(i\text{-Pr})_3$ association, this KTR-PHR occurred at 80 °C in a hexafluoro-2-propanol/dioxane mixture containing $\text{Ag}(\text{OCOCF}_3)_2$ or $\text{Cu}(\text{OCOCF}_3)_2$ to regenerate Pd^{II} species. No arylation was observed in the absence of the oxidant, while the main product was the self-coupling of the aryl iodide in the absence of the phosphine [Eq. (27)]. The formation of the diarylated compound from propiophenone [Eq. (31)] was attributed to a domino process involving four successive

reactions: KTR, PHR, KTR and PHR.^[28] Preliminary studies using 1-bromo-3,5-dimethoxybenzene indicated that aryl bromides would be suitable for the above (KTR-PHR)s.

6.2 Using arenes

In treating a 3:2 mixture of ethyl 2-oxocyclopentanecarboxylate and 1,3,5-trimethoxybenzene with Pd(OAc)₂ catalyst in AcOH/dichloroethane at 50 °C under oxygen, Pihko and co-workers isolated a 1.5:1 mixture of the KTR-PHR and KTR-DHR products.^[71] A survey of different Brønsted acids as additives revealed the strong promotion of the PHR by diphenyl phosphate which, consequently, was used for a number of cross-couplings between β-dicarbonyl compounds and trialkoxybenzenes [Eq. (32)]. The domino reaction was inefficient with arenes bearing two donor groups such as 1,3-dimethoxybenzene but, under modified conditions, occurred with unprotected phenols [Eq. (33)].

From a set of experiments, the authors proposed that the β-arylation of 1,3-dicarbonyl compounds with trialkoxybenzenes occurs via an “early-arylation” pathway (*b*) rather than the usually admitted “late-arylation” pathway (*a*) (Scheme 7).^[71] Diphenyl phosphate would promote the formation of cationic arylpalladium complex **7A**, which would mediate the

dehydrogenation leading to **7B**. The latter would evolve via either arene or hydride insertion to afford **7C** or **7D**, respectively. Subsequent reductive elimination of Pd⁰ would afford the product (**7E**). Note that the delivery of **7E** is accompanied by the formation of either Pd⁰ or Pd^{II}, depending on the reaction pathway. The authors mention a plausible “intercepted-arylation” pathway (c) mediated by diphenyl phosphate, leading to **7B** from **7F**.

Scheme 7. β -Arylation of 1,3-dicarbonyl compounds: “late-arylation” pathway (a) versus “early-arylation” pathway (b) or “intercepted-arylation” pathway (c).

Pihko’s team also studied the KTR-PHR of β -dicarbonyl compounds with indoles.^[29,72] The optimum conditions differ from those disclosed in Eqs (32) and (33), *t*-butyl perbenzoate being the best oxidant [Eq. (34)]. Diastereoselective cross-couplings were effectively performed using 8-phenylmenthyl 2-oxocyclopentanecarboxylate, even with a bromine substituent in the indole nucleus [Eq. (35)].^[29]

Kinetic experiments, isotope effects, deuterated starting materials, 1H NMR monitoring and DFT calculations led the authors to assume the mechanism depicted in Scheme 8 for the cross-coupling between ethyl 2-oxocyclopentanonecarboxylate and *N*-methylindole (**8A**).^[29,72] The proposal highlights the unexpected role of the indole, particularly in the assistance of the dehydrogenation reaction. Indeed, **8A** is involved in the early stage of the reaction as ligand leading to complex **8B**, which mediates the KTR. Trifluoroacetic acid and *t*-butyl perbenzoate jointly assumed the regeneration of **8B**, which also mediates the PHR.

Scheme 8. A KTR-PHR using *N*-methylindole as both ligand and reagent.

7. Domino OHR + KTR + PHR

Piko's team performed three-component domino reactions between β -ketoesters, indoles and aryl boronates under experimental conditions [Eq. (36)] close to those used in the absence of the third component [see Eqs (34) and (35)].^[73] Studies of two-component coupling experiments led to favor a domino reaction involving firstly the coupling between the indole and the arylboronate^[74] and subsequent reaction of the resulting OHR product with the dehydrogenated β -ketoester, as depicted in Scheme 9. Control experiments have nevertheless shown that the KTR-PHR product independently obtained from β -ketoester/indole coupling (see Subchapter 6.2) reacts with the arylboronate to also afford the three-component product, but that would be, at the best, a minor reaction pathway under the three-component domino reactions conditions.

8. Domino HR + KTR (+ HR)

While Heck reaction between phenyl iodide and allyl alcohol led, in most cases, to a mixture of 3- and 2-phenylpropanal, the linear isomer being the major product,^[75] Wang, Li and co-workers, in 2010, succeeded domino (HR-KTR)s leading to cinnamaldehydes with high selectivities from such substrates [Eq. (37)].^[76] The reactions were carried out in the presence of catalytic Pd(OAc)₂, Bu₄NCl and NaHCO₃ in DMSO/DMF with oxygen to regenerate the Pd^{II} species required for the dehydrogenation (Scheme 10).^[38] The HR leads to arylated enolic species **10A**, which coordinates to Pd(OAc)₂ to finally afford the product.

9. Domino KTR + ketonisation + DHR

Tetracyclic compounds have been prepared by Hong's team from the domino reaction of 2-benzylchroman-4-ones and 2-benzyl-2,3-dihydroquinolin-4(1*H*)-ones [Eq. (40)].^[55] These syntheses involve three steps: i) the KTR, ii) the benzylic oxidation and iii) the DHR. Control experiments showed that the benzylic oxidation is mediated by Cu(OAc)₂/O₂. The procedure

allowed the synthesis of Wrightiadione ($Z = O$, $R^1 = R^2 = H$), which is a natural product exhibiting a broad range of biological activities.

10. Domino C(sp³)-H arylation + KTR + HR (+ DHR)

In 2001, Miura and co-workers reported the first domino reaction related to the topic of the review. Three Pd-catalyzed reactions of propiophenone were involved, α -phenylation, dehydrogenation and Heck reaction, which successively arose in a basic media at 160 °C with Pd(OAc)₂/PPh₃ as the catalytic system [Eq. (41)].^[78] The first step of the process is well known with reports from the Miura, Buchwald and Hartwig teams.^[79,80] Mechanistically, the α -phenylation occurs through a phenylpalladium enolate, which provides the α -phenylated product upon reductive elimination.

An extensive domino reaction arose from butyrophenone leading to the formation of up to five C-C bonds [Eq. (42)].^[78] The successive steps, which require either Pd⁰ or Pd^{II} catalyst, are proposed in Scheme 11. Under the reaction conditions, triphenylphosphine may mediate the reduction of Pd(OAc)₂,^[81] while PhBr forms active Pd^{II} species from Pd⁰.^[31] The first reaction of butyrophenone would be either the dehydrogenation or the α -phenylation leading to **[11A]** or **11B**, respectively. The triphenylation product **11C** is issued either from **[11A]** or via the dehydrogenation product **[11D]** of **11B**. Both pathways involve double bond isomerization and multiple Heck reactions, the isomerization being probably Pd^{II}-catalyzed^[82] but, given the reaction temperature, Pd⁰ species could also be involved.^[83] HR of **11C** affords **11E**, which may suffer Pd⁰-catalyzed *ortho*-phenylation of the benzoyl group^[84] to deliver **11F**. Another plausible pathway for the latter is *ortho*-phenylation of **11C** leading to **[11G]**, followed by HR. Triphenylnaphthalenone **11H** could be obtained from intramolecular DHR

of **11C**.^[85] The process was extended to other substrates but only the main products were characterized [Eq. (43)].

Scheme 11. Domino reaction of butyrophenone. The numbers in square brackets correspond to suspected intermediates.

11. Domino C(sp³)-H arylation + KTR (or KTR + HR) + HR + C(sp²)-H amidation

Preparation of 4-aryl-2-quinolinones from the treatment in *t*-amyl alcohol of *N*-(2,3,5,6-tetrafluoro-4-(trifluoromethyl)phenyl)propionamides with aryl iodides, silver carbonate and catalytic amounts of both PdCl₂ and 2,5-lutidine was discovered by Yu's team [Eq. (44)].^[86] The efficiency highly depends on both ligand and *N*-aryl group. Indeed, the process stopped at the level of the first arylation in the absence of lutidine, or led to lower yields with other *N*-aryl groups [Eq. (44)].

The authors considered that these domino reactions involve a triple C-H activation, and proposed the C(sp³)-H arylation of the amide followed by a KTR leading to intermediate **12A** (Scheme 12, path *a*). This arylation regioselectivity contrasts with that of propiophenone [Eq. (41)]. The amide group could favor the β-C(sp³)-H activation, but the mechanism studies of the arylation of ester enolates summarized in Sub-chapter 6.1 (Scheme 6)^[69] leads us to suspect a KTR-HR as another plausible pathway (Scheme 12, path *b*). HR of **12A** affords **12B** via *syn* insertion of C=C bond into the Ar²-PdI bond, rotation around the C-C bond and *syn* β-H elimination.^[87] Subsequent intramolecular C-N bond formation by Pd^{II}-catalyzed dehydrogenative coupling gives **12C**.^[88,89] The proposed **12A** to **12B** pathway is consistent with the arylation of β-substituted propionamides depicted in Eq. (45). Indeed, this stereospecific domino reaction would occur via KTR-HR and then dehydrogenative cyclization rather than C(sp³)-H arylation followed by KTR and subsequent dehydrogenative cyclization.

Scheme 12. Plausible catalytic pathways leading to 2-quinolinones from propionamides.

12. Conclusion

The Pd-catalyzed domino dehydrogenation/enone functionalization are often included in domino multi-reactions, thus in processes with increased values. Indeed, the green and economic interests of a domino reaction is correlated with the number of bonds efficiently created during the process. Most domino reactions above highlighted occur under routine laboratory conditions and are not limited to a few examples. Moreover, some of them are carried out under enantio- or diastereoselective conditions, or afford products with structural complexity. Thus, these domino reactions belong to the toolbox of synthetic organic chemists. The mechanism of the different steps is often attributed with good confidence but a few remain matter of debate. It is plausible that other functionalizations ascribed, in the literature, to a $\beta\text{-C}(\text{sp}^3)\text{-H}$ activation could, in fact, arise through a dehydrogenation pathway.
